SUMMARY

Citrus canker is an important disease of citrus, whose causal agent is the bacterium *Xanthomonas citri* subsp. *citri* (*Xcc*). In previous studies, we found a group of *Xcc* mutants, generated by the insertion of the Tn5 transposon, which show impaired ability to attach to an abiotic substrate. One of these mutants carries the Tn5 insertion in *hupB*, a gene encoding a bacterial histone-like protein, homologue to the beta subunit of the Heat-Unstable (HU) nucleoid protein of *Escherichia coli*. These kinds of proteins are necessary to maintain the bacterial nucleoid organization and the global regulation of gene expression. Here, we characterized the influence of the mutation in *hupB* regarding *Xcc* biofilm formation and virulence. The mutant strain *hupB* was incapable of swimming in soft agar, whereas its complemented strain partially recovered this phenotype. Electron microscope

imaging revealed that impaired motility of hupB was a consequence of the absence of the flagellum. Comparison of the expression of flagellar genes between the wild-type strain and hupB showed that the mutant exhibited decreased expression of fliC (encoding flagellin). The hupB mutant also displayed reduced virulence compared to the wild-type strain when they were used to infect Citrus lemon plants using different infection methods. Our results therefore show that histone-like protein HupB play an essential role in the pathogenesis of Xcc through the regulation of biofilm formation and biosynthesis of the flagellum.

INTRODUCTION

Citrus canker, one of the most important diseases of citrus trees, leads to defoliation, dieback and fruit drop, reducing yields and causing serious economic losses (Graham et al., 2004). Its causative agent is Xanthomonas citri subsp. citri (hereafter Xcc), a member of the Gamma subdivision of Gram-negative proteobacteria (da Silva et al., 2002). This pathogen enters the host plant tissues through stomata or wounds and then colonizes the apoplast, causing corky lesions (cankers) in fruits, leaves and stems. It finally breaks the tissues as a consequence of cell hyperplasia, hence allowing bacterial dispersal (Brunings and Gabriel, 2003). The canker itself, along with surviving populations of bacteria, constitutes the main source of disease spread (Cubero and Graham, 2004). Given the relevance of citrus canker, it is essential to undertake studies that expand the understanding of Xcc virulence mechanisms in order to improve its detection and control.

Bacterial successful infection depends on the ability of the microorganism to adhere to the plant surface, invade the intracellular spaces of the host plant, obtain nutrients, and overcome plant defense (Büttner and Bonas, 2010). Like other plant pathogens, Xanthomonas spp. display an array of virulence factors, such as the synthesis of extracellular cell-wall degrading enzymes and the production of xanthan, the characteristic extracellular polysaccharide (EPS) of this genus, which
contribute to the interaction with plants (Tang et al., 199; Vojnov et al., 1998). The production of these factors is under the control of the rpf/DSF cell-to-cell chemical communication system (Barber et al., 1997; Crossman and Dow, 2004; Dow et al., 2003; Siciliano et al., 2006; Tang et al., 1991; Torres et al., 2007).

Biofilm formation plays a key role in the induction of disease symptoms during Xcc infection. Biofilms are complex assemblies of bacteria usually attached to a solid surface (abiotic or biotic) and encapsulated in a matrix consisting mainly of EPS, proteins, extracellular DNA and lipids (Flemming and Wingender, 2010). In phytopathogenic bacteria, biofilm development contributes to the maintenance of a critical mass of bacteria in specific areas that facilitate the infection process. Moreover, these bacterial assemblages confer resistance to harsh environmental conditions, protection to protozoa attack, tolerance to antimicrobial agents, and consortia metabolism, and also enable horizontal gene transfer (Bogino et al., 2013; Danhorn and Fuqua, 2007). Biofilm formation, which has been extensively studied in many species, consists of five general stages: an initial and reversible attachment, followed by an irreversible attachment that leads to the formation of a monolayer, the development of microcolonies that mature in complex macrocolonies (with the characteristic mushroom shape), and the dispersal of cells in the planktonic state (Kierek-Pearson and Karatan, 2005; Martinez and Vadyvaloo, 2014; Sauer et al., 2002; Stoodley et al., 2002).

Biofilm formation process in Xcc requires the EPS, xanthan, for the development of mature structures both in vitro and in vivo (Rigano et al., 2007). In many species of Gram-negative bacteria, flagella are essential during the early stages of biofilm formation (Guttenplan and Kearns, 2013; Haiko and Westerlund-Wikström, 2013; Wood, 2013). In particular in Xcc, it was shown that flagella are also involved in structuring the mature biofilm with defined water channels and play a vital role in bacterial dispersal, and thus are required for the establishment of bacterial communities on the leaf surface (Malamud et al., 2011).

To better understand the whole mechanism of biofilm formation, it is necessary to know the genetic determinants and underlying factors that regulate this process. To this end, Xcc mutant libraries have been screened in search of new genes involved in biofilm development. Using this tool, Li and Wang (2011) found 33 novel genes related to regulatory networks, EPS production, and lipopolysaccharide synthesis, among others. In our laboratory, a library of Xcc mutants obtained by the insertion of the Tn5 transposon was screened in search of those affected in the adhesion to an abiotic substrate (Malamud et al., 2013). As a result, we found 23 novel genes associated with biofilm formation in Xanthomonas spp.; four of them related to the regulation of gene expression, five encoding membrane proteins, eight encoding structural proteins and six encoding hypothetical proteins. From this screening, we selected the strain characterized in this work, affected in the expression of hupB (XAC1081).

The XAC1081 gene, hupB, encodes a bacterial histone-like protein, homologous to the beta subunit of the Heat-Unstable (HU) nucleoid protein (da Silva et al., 2002). Histone-like proteins in bacteria are able to bind to DNA and are known to contribute to the organization of the bacterial “nucleoid” (Rouvière-Yaniv and Gros, 1975). In addition, they are associated with cellular processes such as replication, recombination and DNA repair, and the global regulation of gene expression (Dorman and Deighan, 2003). Histone-like proteins have been divided into four major groups, based on their amino acid sequence: histone-type Escherichia coli U93 (HU), nucleoid structuring histone (H-NS), integration host factor (IHF), and factor for inversion stimulation (FIS) (Anuchin et al., 2011). HU and H-NS are the best characterized. HU does not recognize a specific sequence when binding to DNA but prefers regions with distorted or supercoiled structures (Dorman and Deighan, 2003). It is believed that the functional role of HU is to participate in DNA supercoiling (Tanaka et al., 1995). In E. coli, HU consists of two subunits, hupA and hupB, acting as a hupA-hupA homodimer or as a hupA-hupB heterodimer, depending on the bacterium growth phase (Balandina et al., 2001; Grove, 2011). In most bacteria, HU is a homodimer. In E. coli, HU null mutants have a mild phenotype, whereas in
Gram-positive bacteria, such as *Bacillus subtilis*, HU appears to be essential (Grove, 2011). In addition, it has been described that HU participates in the regulation of genes involved in processes related to virulence (EPS production, mobility and expression of virulence factors) and tolerance to different types of stresses (anaerobiosis, medium acidification, osmolarity increase, UV radiation, etc.) (Balandina *et al.*, 2001; Nishida *et al.*, 1997; Oberto *et al.*, 2009).

The main objective of this work was to analyze the role of a *hupB* homologue gene in *Xcc* biofilm formation and virulence. We found that a null mutation in the histone-like protein HupB results in a reduction in the ability of the bacterium to infect *Citrus*. In addition, the *hupB* null mutant is impaired in flagellum synthesis being unable to develop a mature biofilm structure. Here, we provide new insights into gene regulation by studying for the first time the role of a histone-like protein in *Xcc*.

**RESULTS**

**The *hupB* gene encodes a bacterial histone-like protein**

The null mutant in *hupB* was isolated from a screening of a pool of *Xcc* 306 mutants (carrying the insertion of Tn5) that aimed to identify those genes required for cell attachment to an abiotic substrate (Malamud *et al.*, 2013). The *hupB* gene encodes a histone-like protein homologous to the beta subunit of the HU protein in *E. coli*. The predicted amino acid sequence shows that, as expected, HupB is a small protein with a predicted molecular weight of approximately 9 KDa. Protein sequence analysis reveals a high conservation among orthologous genes, not only within the same genus (*X. campestris* pv. *campestris*) or related species (*Xylella fastidiosa*), but also in bacteria evolutionarily more distant such as *E. coli* or *Bacillus subtilis* (Gram-positive species) (Figure 1).
Typically, HU adopts a compact conformation by linking the two monomers together (Swinger et al., 2003). Two alpha helices of each monomer form the body of the protein, which is confined by two beta sheets that extend and "embrace" the DNA. An alpha helix (short sequence) completes the structure. According to Lee et al. (1992), a proline residue (P63) is essential in the "coupling" with DNA, and its substitution results in a significant alteration in DNA binding. Another important residue is lysine 3 (K3), which is critical for maintaining a stable complex (Grove and Saavedra, 2002). All of these elements appear to be conserved in the protein encoded by the \textit{hupB} gene (Figure 1).

**A null mutation in \textit{hupB} impacts negatively on the biofilm formation process**

Biofilm formation is a dynamic process which is not only influenced by multiple factors but also involves several stages, from adhesion to the surface until the appearance of mushroom-like arrangements. One of our aims was to evaluate biofilm development in the \textit{hupB} mutant in comparison to the wild-type strain.

In the first instance, we confirmed that there were no major differences in growth between the \textit{hupB} mutant and the wild type strain (Figure S1). Then we analyzed the ability to attach to an abiotic surface of each strain, showing a significant reduction for the \textit{hupB} mutant (approximately 60% less than the wild-type strain) (Figure 2A). The structural organization of the biofilm was studied in detail by Confocal Laser Scanning Microscopy (CLSM). The presence of a mature biofilm formed by the wild-type strain was clearly observed after four days of incubation (Figure 2B). In contrast, the \textit{hupB} mutant strain was only able to grow into seemingly a monolayer of cells, very different from a typical biofilm (Figure 2B). Complementation with an intact copy of the \textit{hupB} gene and its promoter region (\textit{c-hupB}) partially restored the defective phenotypes (Figure 2).
The absence of HupB affects Xcc motility

The environmental survival and pathogenesis of Xcc are subjected to its ability to move. In addition, motility is one of the determinants for biofilm formation. Therefore we investigated if the absence of HupB affects bacterium motility. To this end we performed a swimming assay, in which soft agar plates were inoculated with aliquots of exponential phase cultures of the different strains. After 72 h of incubation, the hupB mutant was essentially non-motile, whereas the wild-type strain showed a migration area around the plating site (Figure 3). Complementation of hupB mutant strain restored the ability to swim, although not reaching the levels of the wild-type strain.

The absence of HupB leads to the loss of flagellum

Since the hupB mutant strain was non-motile, we hypothesized that this could be associated with a defect in either the functioning or a structural defect of flagellum. Therefore, we examined the flagellar apparatus of exponentially growing cells by transmission electron microscopy (TEM). As shown in Figure 4A, a single polar flagellum was visible in the wild type and in c-hupB but not in most of the observed fields for the hupB mutant strain. These results suggest a possible role of HupB in the regulation of flagellar biosynthesis.

Flagella-dependent motility in Xanthomonas spp. is controlled by the hierarchical expression of a regulatory cascade involving several regulators (Yang et al., 2009). Thus, we compared the expression of some of these genes between the wild-type strain and the mutant strain by qRT-PCR (Figure 4B). According to our results, fliC, a class III gene which encodes flagellin, was significantly reduced in comparison with the wild-type strain. Genes encoding FleQ and RpoN2, class I master regulators that control the expression of class II genes, showed no significant differences between strains. By contrast, the flgM gene, encoding a class I master regulator, showed a significant reduction of its expression in the mutant strain when compared to the wild-type strain. The levels of expression of the class II genes (fliA, flhA and fleN) displayed no differences between strains.

This article is protected by copyright. All rights reserved.
Complementation with an intact copy of the hupB gene and its promoter region (c-hupB) restored the expression of fliC and flgM genes to levels similar to those in the wild-type strain (Figure 4B).

HupB affects Xcc pathogenicity

To study a possible effect of the hupB gene product in Xcc virulence, we carried out pathogenicity assays in lemon plants (Citrus limon cv. genova). Two different types of infection methods were applied (Figure 5A): swabbing bacterial suspensions i) on the lower surface (abaxial) of healthy young leaves; or ii) on leaves previously injured with a needle to allow bacteria to enter the mesophyll. Symptoms were evaluated at 30 days post infection (d.p.i.). Results showed that regardless of the infection method used the null hupB mutant strain generated fewer lesions than the wild-type strain (Figure 5A). By contrast, complementation by expression of the hupB gene under its own promoter (c-hupB) restored the ability to induce cankers to wild-type levels.

Next, we compared bacterial growth in planta (Figure 5B). For this purpose, injured young leaves were swabbed with bacterial suspensions of the hupB mutant strain or the wild-type strain. At 0, 6 and 14 d.p.i., plant tissue was grinded and the number of colony forming units (CFU) per cm² of leaf tissue was determined. Results in Figure 5B show significant differences between strains at 6 d.p.i. At 14 d.p.i., the wild-type strain was able to grow about two fold more than the hupB mutant strain.

DISCUSSION

The hupB gene is homologous to the beta subunit of the HU protein of E. coli. This histone-like protein is a member of family II of DNA binding proteins (DNABII), a group of small proteins involved in the organization and compaction of bacterial DNA (Dillon and Dorman, 2010). HU and
other histone-like proteins in bacteria are now called Nucleoid-Associated Proteins (NAPs). NAPs have been related to the formation of complexes at specific DNA structures, in the processes of recombination, initiation of replication and regulation of gene expression, in addition to their role in DNA compaction and protection. In general, bacteria present multiple NAPs, whose functions usually overlap and are complementary. For example, in *E. coli*, the lack of HU is not lethal, unless other NAPs such as IHF and H-NS are also suppressed (Kayoko *et al.*, 1992). In other bacteria, HU disruption is lethal since they only have one NAP available (Liu *et al.*, 2008; Micka and Marahiel, 1992). In the case of *Xcc*, there are genes in its genome that encode proteins homologous to IHF and H-NS (da Silva *et al.*, 2002). In agreement with this, our results showed that a null mutation in *hupB* was not lethal.

In this work, we attempt to understand why a null mutation in a histone-like protein results in a reduction in the ability of the bacterium to adhere to a surface. To this end, we analyzed structures which could be involved in biofilm formation and found that the mutant in *hupB* does not have a flagellum. However, we cannot reject other defective phenotypes which may contribute to biofilm formation. Notably, Devaraj *et al.* (2015) have recently described a new role of NAPs in biofilm formation in *E. coli*. These authors proposed that *hupB* may have a structural role during biofilm formation as an essential element of the matrix, and that HU, as a DNABII protein, binds to the extracellular DNA of the matrix. These authors also described that the HupB subunit is a necessary and limiting component for the growth and maintenance of biofilm structures.

In the present study, the *hupB* mutant strain was unable to swim due to the absence of flagellum, which was associated with a significant reduction in the expression of *fliC* (a gene encoding the main protein of the filament). This suggests that *hupB* positively regulates the flagellar synthesis in *Xcc*. Similar results had already been reported in *E. coli* by Nishida *et al.* (1997). The double mutant *hupA-hupB* (i.e. mutant in both subunits of the protein) does not produce flagellin.
and as a consequence is non-motile. Nishida and colleagues (1997) also concluded that regulation of flagellar genes expression is at transcriptional level. However, the mechanism by which hupB regulates fliC expression and motility has not been elucidated. Our results indicate that none of the class II genes or class I genes, with the exception of flgM, showed differences in expression between the strains. Compared to the class I and II genes, fliC has reduced expression in the mutant strain (Figure 4B). From studies derived from the analysis of the gal operon of E. coli, it is presumed that HU could induce a DNA looping, thus helping to load or unload negative or positive regulators in specific sites of DNA to either help or block the start of gene transcription (Lewis et al., 1999; Oberto et al., 2009). We suggest that the absence of HU would alter the activity of the fliC promoter directly, causing the loss of accessibility for positive regulators or facilitating the access for negative regulators. HU promotes the compaction of DNA, so its inactivation would alter the structure of the DNA molecule and, as a consequence, the activity of several promoters would be affected.

Considering this hypothesis, i.e. that the hupB gene product affects the supercoiling of DNA (Nishida et al., 1997), its mutation could alter the transcription of other genes that we have not considered in our analysis that are involved in flagellar motility. Nevertheless, the mechanism of synthesis and rotation of the flagellum is complex and involves many factors. HupB could alter motility in many ways, as reported for H-NS in E. coli. On the one hand, H-NS is a positive regulator of the flagellar regulon, binding DNA and promoting the synthesis of the master regulator FlhDC (class I) (Bertin et al., 1994), whereas, on the other hand, H-NS modulates flagella rotation by interacting with FliG, promoting its interaction with Mot proteins (flagellar motor).

In the present study, we found that inactivation of hupB leads to the reduction of bacterial virulence in lemon plants. Swabbing infection on undamaged leaves showed that the hupB mutant strain was less effective in colonizing plant tissue through natural openings, such as stomata (Figure 5A). These observations likely imply that lack of motility impairs bacterial movement in leaf surface and as a consequence limits penetration through stomata pores. Consistently, absence of flagellin was shown to slightly reduce Xcc pathogenicity in lemon leaves (Malamud et al., 2011).
In this work, we focused on the study of the effects of the mutation in the hupB gene (XAC1081) on biofilm formation and virulence of Xcc, and demonstrated that it is essential for both processes. However, more work is needed to understand more precisely how it regulates these functions.

EXPERIMENTAL PROCEDURES

Bacterial strains and growth conditions

Xcc strains were cultured at 28°C with shaking at 220 r.p.m. in PYM (peptone–yeast extract–malt extract) medium (Cadmus et al., 1976) or YMM (Y minimal medium) (Sherwood, 1970). E. coli strains were grown at 37°C in Luria–Bertani (LB) medium (Sambrook and W Russell, 2001). Bacterial growth was measured in a T60UV-Visible spectrophotometer (PG Instrument, Leicestershire, UK) at 600 nm and described as optical density 600 (OD_{600}). When required, antibiotics were added to the growth media in the following concentrations: ampicillin (200 mg/ml), kanamycin (50 mg/ml) and tetracycline (3.5 mg/ml).

Complementation of the Xcc hupB mutant strain

The null mutant hupB was complemented through the introduction of the pLAFR3 plasmid carrying an intact copy of the hupB gene and its promoter region. The hupB gene and its promoter were amplified using primers BamHI-hupB-rv and EcoRI-hupB-fw (Table S1). The PCR product was cloned into the pGEMTeasy vector (Promega, USA) and then digested with EcoRI. The released fragment was ligated into pLAFR3 (Staskawicz et al., 1984), which had been previously digested with the same restriction enzyme. This construct was introduced in hupB mutant strain by biparental conjugation through E. coli S17.
Biofilm formation analysis

*Adhesion assay*

To measure the attachment of bacteria to an abiotic surface, we performed the crystal violet assay described by O’Toole and Kolter (O’Toole and Kolter, 1998). Briefly, bacterial strains cultured overnight in PYM medium were used to inoculate YMM medium (containing 1% w/v of glucose as the sole carbon source) to a final OD$_{600}$ of 0.1. Aliquots of 150 μl of these suspensions were placed in different wells of a polystyrene microtitre plate (Orange Scientific, Braine-l’Alleud, Belgium) and incubated at 28°C for 24 h without shaking. Differences in growth between strains were rejected by determining the OD$_{600}$ of each strain before performing the assay. Initially, the medium was carefully removed from each well with a pipette and wells were then washed with NaCl (0.9% w/v). Then, cells bound to the wells were stained with a 0.1% (w/v) crystal violet solution. After 30 min incubation, the remaining crystal violet solution was removed and wells were washed with distilled water twice. The crystal violet adhered to each well was dissolved in 150 μl of 70% (v/v) ethanol. The absorbance of each well was measured with a 7520 Microplate Reader (Cambridge Technology Inc., Bedford, MA, USA) at 570 nm. Results are expressed as the ratio between crystal violet absorbance at 570 nm and growth (OD$_{600}$).

*In vitro analysis of biofilm formation by confocal laser scanning microscopy (CLSM)*

All strains were cultured in PYM medium (supplemented with the corresponding antibiotic) at 28°C. Cultures were diluted 1:1000 in YMM medium and aliquots of 500 μl were transferred to chambered coverglass slides containing a 1-mm thick borosilicate glass (no. 155411, Thermo Scientific Nunc Lab-Tek). Bacterial suspensions were cultured in those chambers for four days at 28°C without shaking until analysis (Malamud et al., 2011). To visualize samples, bacteria were stained using the BacLight LIVE/DEAD viability kit (Thermo Fisher Scientific, Waltham, MA, USA). This kit consists of two different fluorescent dyes: Syto-9t (S-9) (highlighting viable bacteria) and propidium iodide (indicating dead cells). Biofilm formation was studied through an inverted confocal...
laser scanning microscope Nikon Eclipse TE 2000-E2 (Nikon, Melville, NY, USA). Three-dimensional images were generated with *Image J* 1.49 software from the National Institutes of Health (http://rsbweb.nih.gov/ij/download.html).

**Swimming motility assays**

Swimming assays in soft agar were carried out as described in Malamud et al. (2011). Bacteria were cultured in PYM medium overnight and an aliquot (3 μl) of each strain was placed in the centre of Petri dishes containing NYGB medium - 0.5% (w/v) peptone extract, 0.3% (w/v) yeast extract and 16 ml/l glycerol - 0.25% (w/v) agar. The growth of each culture was normalized by OD$_{600}$. Plates were incubated at 28°C and images were taken 72 h later.

**Study of bacterial flagella by electron microscopy**

To obtain TEM images, Formvar-coated copper grids were floated on a drop (5-10 μl) of appropriately diluted bacteria for 1 min. After that, the grids plus absorbed bacteria were then rinsed rapidly with distilled water and floated on a solution of uranyl (2%) for 30 s. Then, the grids were removed with forceps, rinsed with distilled water and the excess liquid was drained off with the edge of a filter paper and preparations were air-dried for 5 min. Finally, the specimens were examined with a Zeiss LEO906 TEM (Carl Zeiss, Oberkochen, Germany) (operated at an accelerating voltage of 100 kV) and photographed with a Megaview III camera (Olympus, Center Valley, PA, USA).

**Gene expression analysis by RNA extraction, cDNA synthesis and qRT-PCR**

*Xcc* strains were cultured in PYM medium until they reached an OD$_{600}$ between 1 and 1.5. Bacteria were harvested, and total RNA was extracted by treatment with TRIZol (Thermo Fisher Scientific), following the manufacturer’s instructions. Total RNA was quantified by spectrometry and its integrity was checked by agarose gel run.

This article is protected by copyright. All rights reserved.
Total RNA was reversely transcribed using random primers and M-MLV RT (Promega). All primers used in this work (Table S1) were designed with the software Primer Express 3.0 (Applied Biosystems, Foster City, CA, USA). Reactions were performed using SybrGreen master mix (Roche, Mannheim, Germany) and a Step One Real Time-PCR system (Applied Biosystems) as previously described (Yaryura et al., 2015). The protocol for the qRT-PCR reactions was as follows: 50°C for 2 min, initial denaturation at 95°C for 5 min followed by 40 cycles of 10 s at 95°C and 30 s at 60°C. qRT-PCR data analysis and primer efficiencies were obtained using LinReg PCR software (Ramakers et al., 2003). The 16S gene was used to standardize the expression of a given target gene; then a ratio between treatments was calculated using the algorithm developed by Pfaffl (Pfaffl, 2001). Relative expression ratios and statistical analysis were performed using fgStatistics software interface (J. A. Di Rienzo, personal communications). The cut-off for statistically significant differences was set as P value < 0.05, indicated as *.

**Plant growth conditions and pathogenicity assays**

The host plant in this work was *C. limon* cv. genova. Plants were kept under controlled humidity and temperature (28-30°C) with a photoperiod of 12 h.

To carry out infection assays, bacteria were cultured in PYM medium supplemented with the appropriate antibiotic overnight. Aliquots of these cultures were diluted in distilled water to a final concentration of 1x10^6 CFU/ml. These bacterial suspensions were swabbed on the abaxial face of intact young leaves or previously injured leaves. Symptoms were observed at 30 d.p.i.

Bacterial growth *in planta* was quantified as previously described (Malamud et al., 2012). Briefly, bacterial suspensions of known concentration (1 x 10^8 CFU/ml) were swabbed on injured lemon leaves. Three samples were taken for each strain at 0, 6 and 14 d.p.i. Bacterial counts were determined by macerating 1-cm² leaf disks in 0.5 ml sterile water. Suspensions were subjected to
serious dilutions and cultured in medium-rich plates with the corresponding antibiotic. Plates were incubated at 28°C, and colonies quantified after 48 h. Population data were transformed to $\log_{10}$ values, and standard errors were determined.

On the left: intact leaves were infected by swabbing with bacterial suspensions of the wild-type strain (Xcc 306), the hupB null mutant (hupB) or the complemented strain (c-hupB) at a final concentration of 1x10^8 CFU/ml; on the right, leaves were injured before swabbing. Pictures were taken at 30 d.p.i. (b) In vivo growth of the Xcc strains in lemon leaves. Bacterial suspensions (1x10^6 CFU/ml) were swabbed on previously injured leaves. Bacterial counts were determined at 0, 6 and 14 d.p.i. Three independent experiments were carried out and similar results were observed.
Fig. 1. Multiple alignment of the HupB protein in Xcc and its homologues in other species. Alignments were carried out applying the Clustal X 2.1 software. Identical residues are indicated with an asterisk (*), highly conserved (•) and less conserved (••). Grey boxes indicate the sequences of the three of the α-helix structures. The proline residue (that intercalates into DNA) is shown in a black box. References and NCBI protein ID: xcc306_hup, X. oryzae pv. oryzae strain 306 (AAAM5953); xcc1044_HU, X. campestris pv. campesiris strain 8004 (AAVS0306); E. coli_bhs, B. subtilis strain 168 (NP_368189); E. coli_hB, hupB of Escherichia coli strain K-12 MG1655 (NP_414974); E. coli_hA, hupA of E. coli strain K-12 MG1655 (NP_418428); Xfa, X. fastidiosa strain 9aSc (AAF84000).

Figure 2. Biofilm formation analysis of the Xcc hupB mutant strain. (a) Microtiter plate adhesion assay. Crystal violet absorbance (Abs 570 nm), OD600 ratio are represented for each strain: wild-type strain (Xcc 306), null mutant strain (hupB) and the complemented strain (c-hupB). Error bars indicate standard error of the mean of three independent experiments. (b) Biofilm structures after four days of inoculation; projections in the x-y plane obtained through CLSM (40X magnification); z-axis projected images are shown below (scale bars = 5 μm).

Figure 3. Swimming motility assay. Aliquots (3 µl) of each culture (Xcc 306, hupB and c-hupB) in exponential growing phase were placed in the centre of a Petri dish containing NYGB-soft agar media. Plates were incubated at 28°C for 72 hours and then, pictures were taken.

Figure 4. Study of the flagellar structure in the hupB null mutant. (a) Images obtained by transmission electron microscopy of the flagellar structure of the wild-type strain Xcc 306, hupB mutant strain and the c-hupB strain. Bacteria were cultured in rich medium and harvested when OD600=1 was reached. Scale bar = 0.5 µm. (b) Relative expression of flagellar genes (flaC, flaA, flaM, flaN, flaA, flaO, rpoN2, flaA) between the treatment (hupB mutant strain or the c-hupB strain) and the control (wild-type strain Xcc 306) was estimated by qRT-PCR. Data correspond to the average of four independent experiments; error bars indicate standard error. Significant difference between treatment and control is indicated by * (p<0.05).
Fig. 5. Pathogenicity assay in C. limon plants. (a) Development of disease symptoms in lemon leaves. On the left: intact leaves were infected by swabbing with bacterial suspension of the wild-type strain (Xcc 306), the hupB null mutant (hupB) or the complemented strain (c-hupB) at a final concentration of 1x10^8 CFU/ml; on the right, leaves were injured before swabbing. Pictures were taken at 30 d.p.i. (b) In vivo growth of the Xcc strains in lemon leaves. Bacterial suspensions (1x10^8 CFU/ml) were swabbed on previously injured leaves. Bacterial counts were determined at 0, 6 and 14 d.p.i. Three independent experiments were carried out and the same results were observed.
